The species richness of voles (Microtinae) and their distribution are poorly known, especially in Europe, where the family has been placed by some authors only within the Cricetidae tribe Arvicolini. One hundred and fifty seven Microtus species are currently recognised, and many of them are well-recognized species, while others remain morphologically undescribed. This taxonomic state of affairs has favoured the need for revisionary analyses in order to (i) better understand the evolutionary history of the family, (ii) make better use of the available genetic information, and (iii) better determine the evolutionary origin of the family. To this end, we generated a multilocus phylogenetic tree using all available mitochondrial and nuclear genes to evaluate the current classification and to assess whether the current division of the genus Microtus (six subgenera, approximately 30 species) is well supported. In particular, we paid special attention to the relationships between the subgenera Microtus, Ondatra, and Myodrini, and to the origins of the genus Microtus. The results indicate that the subgenera Cricetulus, Ondatra, and Myodrini do not form a monophyletic group, while the taxonomy of Microtus is not at all well understood. The phylogenetic results are in contrast to the current taxonomy, which is based on taxa with different geographic distributions. Moreover, they indicate the presence of a very ancient radiation of voles in Central Europe, which is not well sampled in many parts of 2d92ce491b
